Abstract—The aim of the study was to construct linear regression and multiple regression models, describing the dependence of PM$_{10}$ particulate concentration in the city of Sosnowiec on selected meteorological elements: air temperature, precipitation and wind speed. Three multiple regression models were constructed: a generic variant without regard to the barometric situation, and two models separately for high-pressure and low-pressure situations. The data used in the study were the average daily concentrations of PM$_{10}$ registered during the 2013–2015 heating seasons at the Sosnowiec station on Lubelska Street, belonging to the Air Quality Monitoring System operated by the Voivodeship Environmental Protection Inspectorate in Katowice.

Key-words: air quality, particulate matter, regression model, heating season

1. Introduction

Poland is one of the countries with the worst air quality in Europe, with PM$_{10}$ levels very often exceeding acceptable levels (European Environment Agency, 2016). Excessively high PM$_{10}$ concentrations are noted during the heating season in nearly the entire country. Smog, i.e., extremely high concentrations of suspended particulates, is a common phenomenon that is harmful to human health. An association is observed between PM$_{10}$ concentrations and emissions
of pollutants from industry, transport, and home furnaces. However, the concentration of air pollutants is also influenced by local meteorological elements, such as air temperature, wind speed, precipitation, and the type of atmospheric circulation (Majewski, 2005; Czarnecka and Kalbarczyk, 2008; Leśniok and Caputa, 2009; Niedźwiedź and Małarzewski, 2016). This study deals with the concentration of PM$_{10}$ particulates registered in the city of Sosnowiec in the central part of the Silesian Voivodeship.

Analyses of the dependence of concentrations of air pollutants on meteorological elements are frequently carried out using statistical methods. A common solution is to construct models based on linear regression or multiple regression analysis.

The aim of the study was to compare the accuracy of linear regression models and multiple regression models constructed in generic, anticyclone, and cyclone variants.

### 2. Materials and methods

The input data for the study were average daily PM$_{10}$ concentrations recorded at the Air Quality Monitoring System station, managed by the Voivodeship Environmental Protection Inspectorate and located on Lubelska Street in Sosnowiec, as well as meteorological data for nearby Katowice, obtained from the Institute of Meteorology and Water Management. Data pertaining to PM$_{10}$ concentrations and meteorological elements were considered in conjunction with data on the type of pressure system, determined according to the calendar of circulation types by Niedźwiedź (Niedźwiedź, 1981; Leśniok, et al., 2010). The analytical method chosen was the construction of linear regression models describing how the PM$_{10}$ concentration depends on air temperature, wind speed, and precipitation, and multiple models that take into account all of these elements at the same time. Three multiple models were constructed: a generic model taking into account all situations, regardless of the type of pressure system, and separate models for both high and low pressure systems. The first stage of the study was the construction of linear regression models between PM$_{10}$ concentration and each of the above-mentioned meteorological elements. The R$^2$ coefficients obtained were compared to the R$^2$ coefficient for multiple regression. Then, using only multiple regression, which produced more accurate results, anticyclone and cyclone situations were compared. It is widely accepted that changes in concentrations of air pollutants are seasonal (Majewski, 2007; Czarnecka and Nidzgorska-Lencewicz, 2010). Norms are very frequently exceeded during the heating season, when low-quality fuels are burned in home boilers, which are often outdated. Taking into account the variability of PM$_{10}$ concentrations during the year, the months of the heating season (January, February, March, April, October, November, and December) in 2013–2015 were selected for the study period.
3. Results

For all recorded PM$_{10}$ concentrations in the heating season, the mean value was 50.9 µg/m$^3$ with a standard deviation of 29.6 µg/m$^3$. The coefficient of variation was 58.1%. During the study period, anticyclone situations accounted for 54.7%. The mean PM$_{10}$ concentration in anticyclone situations was 55.3 µg/m$^3$, with minimum and maximum concentrations of 16.0 and 235.0 µg/m$^3$, respectively. The standard deviation of the anticyclone population was 32.0 µg/m$^3$, and the coefficient of variation was 56.3%. Cyclone situations accounted for 45.3%, with mean, minimum, and maximum PM$_{10}$ concentrations of 45.2, 10.0, and 177.0 µg/m$^3$, respectively. Taking into account the standard deviation of the population of cyclone situations of 25.0 µg/m$^3$, the coefficient of variation was 55.3%. PM$_{10}$ concentrations in the 2013–2015 heating seasons were characterized by a relatively high degree of variability, showing slightly greater variation during cyclone situations. Acceptable levels were exceeded on 40.0% of days. The 24-hour permissible limit of PM$_{10}$ is 50.0 µg/m$^3$ (Regulation of the Minister of the Environment of 24 August 2012 on the levels of certain substances in the air (Journal of Laws of 2012 item 1031)). In all months of the study, the maximum value exceeded the permissible limit. Table 1 presents the minimum, average, and maximum PM$_{10}$ concentrations during the research period.

Linear regression with respect to individual meteorological elements, i.e., air temperature, precipitation, and wind velocity, shows statistical significance at $\alpha=0.05$ in all cases, but the coefficients of determination $R^2$ are low: 8.0%, 3.4%, and 24.6%, respectively (Fig. 1). The fit at this level is unsatisfactory.
Fig. 1. Regression relationships between PM$_{10}$ concentration and air temperature, precipitation and wind speed in each month of the heating season (January, February, March, April, October, November, and December) in Sosnowiec, in 2013–2015.

In order to obtain a better fit, a regression model was constructed according to dependency 1 at significance level $\alpha = 0.05$:

$$y = T \cdot x_1 + P \cdot x_2 + V \cdot x_3 + x_4,$$  \hspace{1cm} (1)

where:

- $y$ – PM$_{10}$ concentration, $\mu g/m^3$,
- $T$ – air temperature, $^\circ C$,
- $P$ – precipitation, mm,
- $V$ – wind velocity, m/s, and
- $x_1...4$ – multiple regression coefficient.
Multiple analysis taking into account all three meteorological elements resulted in an $R^2$ coefficient of 33.8%, which is still a relatively low value, but much higher than in the previous cases. In addition, air temperature, precipitation, and wind speed all proved to be statistically significant in the model. Analogous regression models were constructed separately for low and high pressure systems. The results are presented in Table 2.

The models for high- and low-pressure systems produced similar values for the coefficient of determination $R^2$, at a level of 30.2% for high systems and 35.9% for low systems. These values do not differ significantly from the generic model. It is worth noting, however, that in the case of the low-pressure model, the rainfall parameter was statistically non-significant. This may be due to the fairly small data population in comparison with the other regression models. It can be concluded that construction of a general model is sufficient for analysis of the relationship between PM$_{10}$ concentration and meteorological elements. Breakdown into high- and low-pressure systems does not lead to either a significant decrease or increase in accuracy, but requires more labour.

4. Discussion and conclusions

In Sosnowiec, during the 2013–2015 heating seasons, permissible PM$_{10}$ levels were exceeded on 40.0% of days. Similar results were obtained for this city in other studies (Cembrzyńska et al., 2015). In all months of the study, the maximum value exceeded the 24-hour permissible limit of PM10, which is 50 $\mu$g/m$^3$ (Regulation of the Minister of the Environment of 24 August 2012 on the levels of certain substances in the air (Journal of Laws of 2012 item 1031)). The main objective of the analysis was to compare several variants of models based
on regression analysis. The analysis showed that a multiple regression model is more accurate than a linear regression model. Among the variables tested, wind speed had the greatest influence on the level of PM$_{10}$ concentration. PM$_{10}$ concentration has been found to be most strongly correlated with wind speed in other parts of the country as well (Czarnecka and Nidzgorska-Lencewicz, 2008). The multiple regression model taking into account air temperature, wind speed, and precipitation in the 2013–2015 heating seasons resulted in a coefficient of determination of 33.8% on average. Comparable values have been obtained in studies on other areas of Poland (Czarnecka and Nidzgorska-Lencewicz, 2008). The accuracy of the model can be improved by increasing the number of elements taken into account. The literature describes regression models that also include visibility, atmospheric equilibrium, and relative humidity (Ćwiek and Majewski, 2015). The inclusion of more variables in the model could lead to higher coefficients of determination. Irrespective of the approach and the method, determination of patterns in the dependence of concentrations of pollutants on the complex of weather elements and types of synoptic situations can be used in particular to predict high and excessive concentrations on the basis of weather forecasts (Niedźwiedź and Ustrnul, 1989; Niedźwiedź and Olecki, 1994; Ośródka, 1996).

To sum up, the following conclusions can be drawn from the research:

1) Higher accuracy described by the coefficient of determination $R^2$ is achieved using multiple regression models than for linear regression models. On average, the $R^2$ coefficient was 33.8% for multiple regression and 8.0%, 3.4% and 24.6% for linear regression, in the case of air temperature, precipitation, and wind speed, respectively.

2) The optimal solution was to construct a generic multiple regression model ($R^2 = 33.8\%$) based on the entire data set from the 2013–2015 heating seasons. The $R^2$ coefficients from models, constructed separately for high-pressure systems ($R^2 = 30.2\%$) and low-pressure systems ($R^2 = 35.9\%$), did not differ significantly from the coefficient obtained for the general model. The accuracy of the model could be improved by expanding the population of input data and by incorporating additional variables in the model, such as visibility or atmospheric equilibrium.

3) During the 2013–2015 heating seasons, the most significant meteorological element affecting the PM$_{10}$ concentration in Sosnowiec was wind speed, which had the highest statistical significance in the model. Precipitation proved to be the least significant.

4) The relationships demonstrated can be used to predict concentrations and exceedances of permissible PM$_{10}$ levels based on the forecast of meteorological elements.
